ABSTRACT

In this report, we designed a MIPS-like instruction set and implemented a simulator for it. The simulator supports cached memory and pipelined instruction execution. In order to evaluate its performance, we designed several benchmarks and compared the clock cycles under various simulator configurations.

1. INTRODUCTION

This report describes the design and implementation of a RISC instruction set and its simulator. The instruction set is a subset of the MIPS instruction set¹ with some modifications for simplicity. It supports basic instructions such as data transfer, control, integer and floating point computations as well as the advanced feature SIMD. The simulator is implemented in C++ with QT for the GUI. The backbone consists of a hierarchical multi-way associative memory cache system and a pipelined CPU architecture with a Floating Point Unit (FPU) and a Vector Unit (VU). A few benchmarks including exchange sort and matrix multiplication are used to evaluate the performance of the simulator.

The report is structured as follows: in section 2, we will introduce the design of our instruction set and in section 3, we will describe the implementation of the simulator. Then in section 4, we will report the performance evaluation results. At last, we will summarize the lessons learned in section 5.

2. INSTRUCTION SET DESIGN

The instruction set follows the RISC design strategy. It contains 6 types of instructions, i.e., data transfer, arithmetic and logical, control, floating point, cache and SIMD. The data types supported are 8-bit byte, 32-bit word integer and 32-bit single precision floating point. The memory is byte addressable and the byte ordering is big-endian. Word access requires 4-byte alignment.

There are 16 32-bit general purpose registers for integers (gpr[0] - gpr[15]), 16 32-bit registers for floating point (fpr[0] - fpr[15]), and 16 64-bit vector registers for SIMD (vr[0] - v[15]). General purpose and floating point registers can be accessed by load/store instructions. gpr[15] is usually used by control instructions as the default register for storing return address. Vector registers can hold 8 8-bit byte integers simultaneously. The vector element index starts from the most significant bit, that is vr[i][0] is the higher 8 bits of vr[i]. There are also one 32-bit register for program counter (\$pc) and one 32-bit status register (\$status). \$pc cannot be directly accessed and can only be changed by control instructions.

Instructions use fixed length encoding. Each instruction is 32 bits long. The addressing modes are immediate and displacement. The

register index requires 4 bits and the immediate operand can have up to 17 bits. The operation code is 7 bits long. The first 3 bits are used for distinguishing 6 instruction types. Each instruction can have up to three operands. Like in MIPS, depending on the number of operands, there are three kinds of instructions. Format 1 only has an offset field which is up to 25 bits. Format 2 has two register operands and one immediate. Format 3 has three register operands. The instruction format is described in Table 1.

Table 1: Instruction Format

Format	Field (32 bits)				
1	opcode (7)	offset (25)			
2	opcode (7)	\$1 (4)	\$2 (4)	immedi	ate (17)
3	opcode (7)	\$1 (4)	\$2 (4)	\$3 (4)	X

The instruction set has 6 types. Data transfer is in charge of loading/storing value from/to memory. Arithmetic and logical are basic integer computation instructions. They can operate on register operand or immediate value in instructions. Control has jump and branching instructions and also breakpoint for debugging. Floating point instructions perform floating point calculations and also integer conversions. Cache instruction can preload a word into cache without affecting the register files. SIMD instructions can do vector operations and transfer values between integer registers and vector registers. Details about each instruction and its encoding are listed in Table 4.

3. SIMULATOR

3.1 Overview

The simulator follows the classic Model View Control design. A simplified UML of the simulator is shown in Figure 1 which gives an overview of the architecture. A simulator class sits in the middle acting as a coordinator for the rest of the classes. The model part consists of a CPU class and a MemSys class. The CPU class handles most of the instruction executions. It also contains a FPU and a VU for floating point and vector operations. The MemSys controls all the memory accesses. It has a Cache and a Memory as its components. Cache and Memory are both inherited from the Storage class which makes memory hierarchies easy to implement. Three view classes CPUView, CacheView and MemoryView display the CPU, cache and memory statuses. The model-view communications use QT's signal and slot model instead of callback handlers. This makes adding new interactions easier. Besides, Simulator also includes a ConfigDialog class which can change the system setting during runtime. We will introduce each part in detail in the next few sections.

mips64/

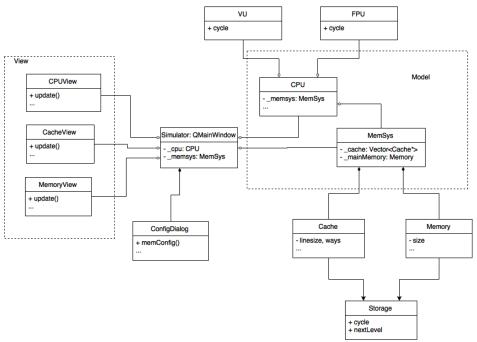

Figure 1: Overview of simulator architecture

3.2 Memory and cache system

We use a hierarchical structure to build the memory-cache system. First, we define an abstract class Storage. Both Cache and Memory inherits from this base class. The Storage class contains an integer field cycle defining the number of cycles it needs to execute an instruction and a pointer nextLevel which references to the next level of storage object, if any. It also supports 3 methods load, store and dump. The load method takes a 32bit integer address, a pointer to the buffer for storing loaded values and the length of data blocks to be read as the arguments. It copies the content in the Storage starting at the input address into the buffer of the same length. The store method takes the same three arguments as the load method. Instead of loading data blocks into the buffer, it takes the content from the buffer and writes them into the blocks from the starting input address. The dump method can convert and concatenate the content in the storage into a string for debugging use.

3.2.1 Memory

The Memory class inherits from the Storage class, it implements the methods inherited from the Storage class straight forwardly. The data is stored in a byte array so that it is byte addressable. The pointer to the next level is set to be a null pointer.

3.2.2 *Cache*

An overview of the cache memory hierarchy is shown in Figure 2. The Cache class supports multiple-way associativity with write back/through and LRU/Random policies. It also inherits from the Storage class and consists of multiple cache lines as the basic building block.

Cache line.

The cache line is defined using the structure Cacheline. It has a boolean field valid which indicates whether this cache line is empty or not, a boolean field dirty which indicates if the content in the cache line is newer than that in the lower level storage. The

lru field indicates its priority in the LRU replacing mechanism. It also contains a pointer data referencing to an array of bytes that served as the data blocks.

The cache consists of a two-dimensional array of Cacheline. The rows correspond to indices of memory blocks and the columns correspond to the ways associated to the same index. The total size of cache is the number of rows times the number of columns. The size of the cache, number of ways and number of index can be set at the initialization stage.

Cache functions.

The inCache method takes an address and returns the cache line position if the address exists in the cache or null if not. Since the memory address starts from 0, it calculates the block index as (address / cache line size) and tag value as (address % cache line size). The block index corresponds to the index in the cache array. The method iterates all the ways of cache lines attached to that index to see if any tag matches the tag of this address. If there is any match, it returns the position of the cache line, otherwise returns null.

The evict method takes a requested address and returns a clean cache line position corresponding to that address. It looks up in the cache line array and searches for any empty lines of that address, which means that the valid flag is false. If such line exists, it returns its position. If all lines are occupied, which means all valid flags are true, it evicts a line according to the replace policies. We have implemented two replace policies: (1) random eviction (2) LRU eviction. Under the former scenario, a random number between [0, number of ways - 1] is generated. If the dirty bit of this cache line is true, which means it contains newer value than the lower level of storage, it will be evicted to the lower level of storage. Then the cache line is emptied and the position is returned. The LRU is implemented as follows. Each cache line at a specific index is assigned an LRU number. When a line at this index is updated, all other lines that have lower LRU numbers are incremented by 1. Then the updated line's LRU number is set to 0. The higher number

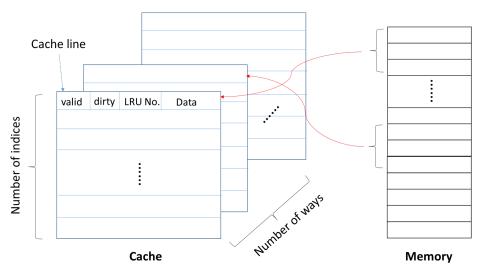

Figure 2: Schematic of memory and cache implementation

means less recently used.

The load method allows us to read a block starting at a specific address in memory. It first checks if the address exists in the current cache level by calling the inCache method. If the returned position is null, there is a cache miss. It will call the the next level of storage's load method, which could be another cache or the memory. The data will be passed along the hierarchical call chain. The newly loaded data have to be written into the cache. An empty cache line is created by calling the evict method. If the returned position is not null, there is a cache hit. The data in the current cache line is loaded and passed up.

The store method allows us to write an array of data blocks into a specific address in memory. First, it also checks if the cache line corresponding to the requested address exists in the cache by calling the inCache method. If yes, it reports a cache hit and copies the data blocks into the current level of cache. Two write policies are implemented: (1) write back (2) write through. In the former scenario, we just set the dirty flag of the cache line to be true and update the LRU numbers. In the latter scenario, we still need to call the store method in the next level of storage to pass the data down. If the address doesn't have a corresponding cache line in the cache, we have a cache miss. The load method is called to bring the data blocks from next level into the cache. Then it's treated as in the cache hit case.

3.2.3 Memory system

The MemSys acts as a mediator between the cache-memory hierarchy and CPU. Both Memory and Cache are encapsulated in it. The MemSys class exposes four methods loadWord, loadByte, storeWord, storeByte for CPU fetching instructions or issuing load/store instruction. It also keeps a countdown integer for CPU clocking. Each time CPU issues an request, it calculates the required cycles to complete that request and only return the result after that many cycles have passed. Internally, MemSys uses a string request keeping the current serving request, if a different request comes in (possible under the pipeline mode), it will not respond until it finishes its current serving request. That means this memory system has only one port and only allows a single access at a time.

The MemSys is also responsible for communication between the Simulator class. Whenever the Memory or Cache changes its internal status, it will emit a notifying signal to the Simulator,

and Simulator will in turn call the update methods in the corresponding view. Simulator can talk to the MemSys to change its configuration. When a user modifies the memory system configuration in the ConfigDialog class, the Simulator will notify MemSys through signaling and MemSys will initialize a new setting of cache-memory hierarchy by calling the init method.

MemSys provides one layer of indirection. It hides the implementation of the cache and memory and makes the interfaces between other classes easier to maintain.

3.3 CPU

The CPU class is where most of the simulation happens. This class keeps a clk field for clock cycle, a pc field for the program counter, and also the register files and pipeline states. It maintains a pointer to the MemSys for memory access and pointers to a FPU and a VU for special instructions. Besides, it can communicate with Simulator to notify the update of CPU status and get the commands from the user interface.

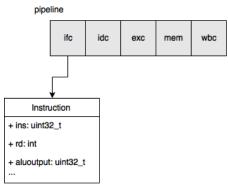

Figure 3: Pipeline structure

3.3.1 Pipeline

The CPU class uses a standard 5-stage MIPS pipeline. Every instruction can be completed in 5 cycles: instruction fetch cycle (ifc), instruction decode cycle (idc), execution cycle (exc), memory access cycle (mem) and write-back cycle (wbc). There are five methods ifc, idc, exc, mem and wbc implementing these cycles. The pipeline pipe is implemented as a array of length 5.

Each position in the array corresponds to an execution stage (see Figure 3). Elements in the array are the structure Instruction. Instruction keeps information about the instruction being executed. It resembles the registers between pipeline stages in hardware. Some key fields are opcode for keeping instruction code, rd1, rd2, rd3, imm for storing operands, stage for indicating execution stage and aluoutput, fpuoutput, vuoutput, lmd for keeping execution result. The execution of an instruction is simulated by passing the structure through the pipe array and filling its fields in different stages.

ifc.

Fetch instructions from MemSys by calling loadWord method and create a Instruction instance. If in a pipelined execution mode, examine the instruction at mem stage to see if it is a branch. If it is a branch and is taken, change the pc accordingly. Otherwise increase the pc by 4. If the next stage in pipe is empty, increase its stage by 1 and pass the structure to the next stage.

idc.

Decode the instruction. First extract the first 7 bits to get the instruction opcode, and then decode the rest operands according to the format (Table 1). After decoding, load operands from register files. If under the pipelining mode, we need to resolve potential data hazards. In the 5-stage pipeline setting, we only need consider read after write (RAW) hazard since the write back cycle is at the last stage and only one instruction can write at a time. Examine every instruction in the pipeline after idc stage and see if its destination register is one of the operands we need to read. If the instruction has finished its execution, we can forward the result in aluoutput (or fpuoutput, vuoutput, lmd) to the operand we need. Otherwise, we need to stall the pipeline, and wait for the operand to be ready. When the operands are ready, we can pass the instruction to the next stage.

exc.

Execute the instruction according to its opcode. If it only needs integer computation, we can finished the execution within the CPU class, otherwise, we need to forward the instruction to FPU or VU for special handling. In CPU, we can do data transfer, arithmetic and logical, control and cache instruction execution. If it is data transfer, we compute the memory address and store it in aluoutput. If it is arithmetic and logical, we save the computation result in aluoutput. And if it is control, we calculate the new pc address and put it in aluoutput. If it is floating point, we forward the instruction to FPU and wait for the result to store in fpuoutput. Similarly, SIMD instruction will be forwarded to VU and result saved in vuoutput. After computation, the instruction is passed to the mem stage.

mem.

This stage is only for data transfer instructions. If it is a load instruction, we load memory use the address stored in alwoutput and put the loaded value into lmd. If it is a store instruction, we store the value in operand to the address in alwoutput. Other types of instructions can directly pass this stage if the next stage is empty.

wbc.

Write aluoutput (or fpuoutput, vuoutput, lmd) to destination registers and destroy the Instruction structure.

The step method calls each stage function in reverse order

(from wbc to ifc) and increase the clk by 1 afterwards. This completes one step of simulation. To simulating the whole program, we can call step until there are no more instructions.

3.3.2 FPU & VU

FPU handles floating point operations. It can simulate multicycle floating point calculations. Internally, it has a cycle and countdown field. Like MemSys, it will only respond requests from CPU after certain number of cycles. Since it is separated from CPU, for future extension, the pipeline can support multi-issue easily. VU deals with vector operations. It also support multi-cycle calculation. Internally, vectors are saved as an array of bytes and computations are element wise. The separation of VU is also for future implementation of multi-issue.

3.4 User interface and use guide

The graphical interface is implemented in QT. A screenshot of the GUI is shown in Figure 5. The main window is the Simulator class. It can be roughly divided into three parts.

The left panel is for displaying CPU status which is implemented by CPUView class. Clock cycle, program counter, register files and pipeline can be seen here. There are also several buttons controlling the simulation. Pipeline on/off button can turn on/off the pipeline. step can simulate one clock cycle. run button executes the program at the speed of 100 millisecond a cycle. In this mode, you can see the changes in CPU or memory system easily. You can also stop the simulation whenever you want. exe button runs the program at machine speed. reset button can clear the pipeline and register files and set the clock and pc to 0.

The middle panel is for visualizing cache. It has tabs for switching between different levels of caches and on the top, there is an on/off button for turning on/off cache. When the cache is turned off, the tab panel will become invisible. This part is implemented by CacheView.

Finally, the right part is MemoryView where you can observe memory data and also change the display format. At the scroll area, you can press the address button and add or remove a breakpoint to the program. If the button is pressed down (turn blue), it means it is a breakpoint.

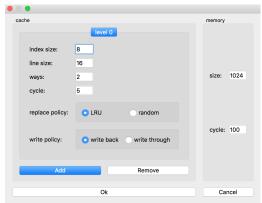

Figure 4: Configuration Dialog

You can change system configurations using the configs menu. After clicking the menu, a dialog (see Figure 4) will show up. New cache and memory configurations can be set here. This dialog is a class of ConfigDialog and is a component of Simulator. The Memory System menu also provides options to dump the memory data into a file or clear the memory. The Program menu provides a way to load program direct into memory.

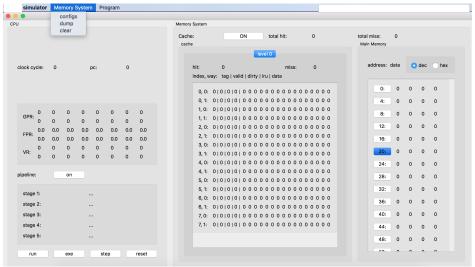

Figure 5: GUI screenshot

3.5 Assembler

The assembler takes the instructions in assembly language and encodes them into 32-bit integers. The assembler executes in two passes. In the first pass, it strips all the comments that starts with # symbol and stores all labels into a label map, which uses the line number as the value. In the second pass, it replaces the labels in other clauses with the relative line numbers and encodes the instructions according to a preloaded map of opcodes. The result is written in binary format into a file.

3.6 Testing

We tested our simulator mainly through GUI. To test the memory system, we wrote a program generating sequential or random memory accessing instructions. Then we use a small driver program to read in these instructions and directly call the interfaces provided by MemSys. For sequence access, we precomputed the final cache-memory state manually and compared with the result produced by simulator. In this way, we found a bug in cache line eviction. For random access, since the result is hard to compute by hand, we only see if a large amount of random accesses will break the program. The simulator has passed this stress test.

To test the assembler, we simply wrote a disassembler and to see the results converted from each side match. We also manually encoded the benchmark program exchange sort to see if the assembler works

To test the pipeline, we designed some small programs with data dependencies and branch hazards. We run the simulator step by step to see if it can handle the hazard correctly. In this way, we found some bugs in implementing branching instructions.

4. PERFORMANCE EVALUATION

4.1 Benchmark

We designed the following benchmark programs: (1) Exchange sort (2) Matrix multiplication (3) Matrix multiplication with SIMD for performance evaluation.

The exchange sort uses the bubble sort algorithm (Algorithm 1). Core part is two level of for loop. We implement the if condition with bgez instruction and the for loop condition with beq instruction.

Matrix multiplication uses a three level of for loop (Algorithm

Algorithm 1: Exchange sort

```
integer array A; l = length of A;

for i from 0 to l - 2 do

| for j from i + 1 to l - 1 do
| if A[i] > A[j] then
| swap A[i] and A[j];
| else
| continue;
| end
| end
```

2). The for loops are also implemented in beq instruction. In the experiment, we will multiply a 4 by 8 matrix with a 8 by 4 matrix.

Algorithm 2: Matrix multiplication

```
left matrix L (4 × 8), right matrix R (8 × 4);

a = number of rows in L, b = number of columns in L;

c = number of columns in R;

Create result matrix res of size a*c, initialized with 0s;

for i from 0 to a - 1 do

for j from 0 to c - 1 do

for k from 0 to b - 1 do

res[i][j] += L[i][k]*R[k][j];

end

end

return res;
```

Matrix multiplication with SIMD uses the same size matrix as above. Since the architecture supports 8-byte vector multiplication, we can preload rows and columns of the matrix into the vector and do the multiplication in one step. The result matrix can be calculated using the formula in Algorithm 3. From experiment results, we can see SIMD saves many CPU cycles.

4.2 Experiment result

We tested our three benchmarks under 10 cache configurations

Algorithm 3: Matrix multiplication with SIMD

```
left matrix L, right matrix R;
Flatten L into a vector v1 of size 8 by rows;
Flatten R into a vector v2 of size 8 by columns;
Create result matrix res of size 4, initialized with 0s;
Create vector v3 with size 8;
for i from 0 to 3 do

for j from 0 to 3 do

v1 = L[i][], v2 = R[][j];
v3 = v1 * v2;
res[i][j] = sum(v3);
end
end
return res;
```

and with or without pipeline being turned on and measured their performance in terms of total CPU cycles being used. Configuration details can be found in Table 2. Memory cycle is assumed to be 100. L1 cache is 5 cycles and L2 cache is 20 cycles. Simulation results are shown in Table 3.

Table 2: Cache Configurations

	level	index size	ways	line size	policy
1	1	4	1	8	-
2	1	4	1	16	-
3	1	4	4	8	LRU
4	1	4	4	8	Rand
5	1	4	4	16	LRU
6	1	4	4	32	LRU
7	2	4,16	1,2	8,16	LRU
8	2	4,16	2,2	8,16	LRU
9	2	4,16	1,2	16,16	LRU
10	2	4,16	2,2	16,32	LRU

From the table, we can see that overall configuration 6 with pipeline achieves the best performance and SIMD is better than using loop for matrix multiplication. Further comparing different results, we can find the following interesting conclusions.

(1) pipeline itself does not provide much improvement. Without cache, pipeline can only provide about 2% cycles reduction. But with cache, it can provide over 10% boost. (2) pipeline may lower the performance if the cache configuration is not right. We observed that cycle numbers increased for cache configuration 2 running the matrix multiplication with SIMD program. The increase of cycle numbers may be due to that two instructions in the pipeline need to access the same cache line but with different memory address. This only happens when cache is direct mapped. (3) cache makes a huge difference for performance. With a bigger and more associative cache, performance can boost over 500%, (for example comparing configuration 1 and 3). (4) finding the right cache configuration is difficult. Generally more associative and bigger cache line size will help. Adding L2 cache does not help much compared with expanding the L1 capacity. (5) LRU is much better than random when the number of ways is large. Comparing configuration 3 and 4, LRU has a huge advantage. (6) program instruction types also play a big role. Programs with more branching and memory access have more potential to be optimized.

5. SUMMARY

We gained lots of experience in designing and implementing a

standalone system from the scratch. A couple of lessons have been learned:

For the experiment result, we learned that pipeline has to work with cache to provide better performance and memory is usually the bottle neck of the program. A good cache will help boosting the performance a lot.

During the implementation of the simulator, we learned that having a good design at first is extremely important. For example, before adapting the signal and slot model and using simulator as a mediator, we used the callback functions and let classes directly talk to each other. After many functions were added, the interaction between them became too complicated to maintain. But usually it is hard to have a good design at the beginning, so redesign early is also very helpful.

We also learned testing is hard and manually written test is not practical and efficient. The memory is relatively easy to test because we can treat it like a black box. But cache and CPU is hard to use blackbox test. Writing test manually is time-consuming and makes it less efficient in debugging.
